ABSTRACT: Supercritical carbon dioxide was used as a reaction medium to synthesize statistically random (i.e., no specific correlation between the location of the monomers on the polymer) copolymers of tetrafluoroethylene (TFE) and vinyl acetate (VAc) with similar molar mass and 11.6–63.3 mol % TFE content. The solubility of the copolymers at 25 °C in CO₂ reduced after reaching a maximum value at a TFE molar concentration of 19.3 mol %. The 46.7 mol % TFE copolymer only dissolved in CO₂ at elevated temperatures, whereas the 63.3 mol % TFE copolymer did not dissolve in CO₂ even at temperatures in excess of 144 °C and pressures of 210 MPa. The molecular modeling results show that the interaction of CO₂ with acetate side group was not affected by presence of fluorine in the polymer backbone; therefore, the enhanced solubility of the semifluorinated copolymers is attributable to the enhanced binding between CO₂ and the semifluorinated backbone of the copolymer when the CO₂ molecule can access both the fluorinated (Lewis base) and hydrogenated (Lewis acid) parts of the backbone simultaneously.

Introduction

Poly(tetrafluoroethylene-co-vinyl acetate) (poly(TFE-co-VAc)) is a fluoropolymer with potential applications in the coatings, optical, and biomedical fields.¹⁻³ Poly-(TFE-co-VAc) can be synthesized via free radical copolymerization of tetrafluoroethylene (TFE) and vinyl acetate (VAc) in dense carbon dioxide, with the composition of the TFE — VAc copolymer being controlled by the ratio of monomers in the feed.⁴ Although a small concentration of fluoro surfactant is added to the monomers and CO₂ in an initial study of this polymerization, subsequent trials without surfactant yielded copolymers of similar polydispersity and greater molar mass, implying that the surfactant is not necessary for solubility of the macroradical chains.⁵ On the basis of reactivity ratios, poly(TFE-co-VAc) is a random copolymer because TFE cross-propagates with VAc, and VAc propagates in such a manner that the sequence of TFE and VAc units in the polymer backbone is randomly ordered (i.e., these polymers are not diblock copolymers composed of a long chain of perfluorooctyl (joined to a long chain of poly(vinyl acetate)). Hydrolysis of VAc to vinyl alcohol (VA) yields the predicted decrease in copolymer molar mass to form poly(TFE-co-VAc-co-VA), suggesting that the copolymer was linear.⁴⁵ This is in contrast to poly(TFE-co-VAc) prepared by emulsion, where a precipitous drop in molar mass is observed upon hydrolysis due to ester groups in the backbone. The high yield and high molar mass of the TFE — VAc copolymers provide indirect evidence that poly(TFE-co-VAc) is CO₂-soluble at reaction conditions of 45 °C and 20–23 MPa and loadings of 20% w/w. Because the polymerization was conducted in a vessel that did not permit detection of the phase behavior, the actual CO₂ solubility of these polymers was not determined.

The phase behaviors of the homopolymers of each monomer have been previously established. Poly(vinyl acetate), PVAc, is a noncrystalline, low-T₀ (glass transition temperature) polymer that exhibits the greatest degree of CO₂ solubility associated with any high molecular weight oxygenated hydrocarbon homopolymer that has yet been identified, although it is far less CO₂-philic than fluorocrylate or siloxane-based polymers.⁶⁻⁷ This high degree of CO₂ solubility has been attributed to a weak complex that forms between CO₂ and the readily accessible acetate group.⁶⁻⁷ PTFE is a crystalline polymer that is insoluble in CO₂ and organic solvents, although it does dissolve at high temperatures in high molecular weight fluorocarbon solvents.⁸ Poly(tetrafluoroethylene-co-19.3 mol % hexafluoropropylene) (FEP₁₉) is a nonpolar fluorocopolymer that has similar properties to PTFE, but FEP₁₉ is highly branched and therefore has normal melting point at ~145 °C, whereas PTFE has a melting point in excess of 300 °C. It has been demonstrated that FEP₁₉ can dissolve in supercritical CO₂ at temperatures in excess of 185 °C and pressures of approximately 100 MPa.⁹⁻¹⁰ If the TFE segments in FEP₁₉ are replaced with vinylidene fluoride (VF), this VF–HFP copolymer remains in solution to very low temperatures since the polar character of the VF group interacts with the quadrupole of CO₂.¹¹ These
phase behavior results suggested that perfluorination does not impart polymers high solubility in CO2. This argument had also been made by Raveendran et al. through molecular simulation; i.e., partially fluorinated molecules provide more favorable binding sites for CO2 than perfluorinated analogues. The objective of this study is to experimentally establish whether random copolymers of TFE and VAc are indeed CO2-soluble at levels in excess of those exhibited by PVAc homopolymer containing a comparable number of repeat units. Poly(TFE-co-VAc) samples are prepared by radical copolymerization in supercritical CO2 without surfactants, and the phase behavior of the copolymers is measured using nonsampling techniques in windowed, variable-volume cells. If the TFE–VAc copolymers are indeed more CO2-soluble than homopolymers of VAc, then molecular modeling will be used to characterize the CO2–polymer interactions in the CO2–PVAc and CO2–poly(TFE-co-VAc) systems.

**Experimental Section**

**Reagents.** All chemicals were purchased from Aldrich (Ontario, Canada) and used as received unless otherwise specified. TFE was prepared by vacuum pyrolysis of PTFE and stored at room temperature over di-limonene in a 300 mL stainless steel sample cylinder fitted with an 12.4 MPa safety rupture disk. [Caution: tetrafluoroethylene is inherently dangerous, and anyone contemplating handling TFE under high pressures should be very familiar with safe handling procedures.] TFE-co-VAc copolymers were synthesized as previously described, with the only difference being the compositions synthesized. As previously described, polymers were synthesized without a surfactant and by radical copolymerization in supercritical fluid CO2 using diethyl peroxycarbonate initiation. Copolymers of TFE–VAc were synthesized with a TFE molar composition from 7 to 63.3%.

**Characterization.** Polymer molar mass was characterized by a GPC (Waters U6K Injector, 510 pump) equipped with a refractive index detector (Waters 2410) and a series of UltraTsgel columns (Waters 10, 10, and 500 Å). Using ethyl acetate or tetrahydrofuran (THF) as the mobile phase at a flow rate of 1 mL/min, polymer molar masses were calculated relative to polystyrene standards. 1H and 19F NMR spectra (Varian Gemini spectrometer) were obtained in CDCl3 at 300.75 and 282.33 MHz, respectively. Elemental analysis was conducted by Guelph Analytical Laboratory Service (Ontario, Canada). Carbon, hydrogen, and oxygen content were measured via combustion analysis (ASTM D5737/D5291), while nitrogren content was determined using the oxygen bomb combustion technique (ASTM D3761). Glass transition temperatures (Tg) were measured using a differential scanning calorimeter (DSC, Q1000), under an inert nitrogen atmosphere, with a heating rate of 10 °C/min and a scanning range of −20 to 100 °C.

The phase behavior of mixtures of CO2 with copolymers of low TFE concentration (11.6–26.5 mol %) was studied using a variable-volume view cell. Known amounts of the solid poly(TFE-co-VAc) were loaded into the sample volume. The mass of CO2 was determined from the displaced volume, temperature, and pressure using an equation of state for carbon dioxide. The initial concentration of each copolymer was 20 wt %. The copolymer–CO2 mixture was then compressed to 67 MPa and mixed with a magnetically driven impeller (DBR Design & Manufacturing Inc., model no. 274152, designs 0.0007), and the poly(TFE-co-VAc) solubility in CO2 was followed. If two-phase solid–liquid equilibrium was observed, then additional CO2 was introduced to the sample volume until the copolymer concentration decreased by approximately 1 wt %. If a single, transparent phase was attained, the two-phase boundary was determined by slowly expanding the sample volume until a second phase appeared, as evidenced by the sample volume becoming opaque due to the formation of dispersed liquid copolymer droplets throughout the sample volume. The mixed phases were then allowed to separate until two transparent phases were observed. It was also determined whether the second phase was composed of solid particles or droplets of a copolymer-rich liquid phase. The appearance of a copolymer-rich liquid phase would be indicative of copolymer melting point depression in the presence of dense CO2, a phenomenon associated with highly CO2-soluble polymers and compounds. The pressure at which the second phase appeared was considered to be a dew point if a small copolymer-rich phase settled to the bottom of the cell. Two-phase pressures were reproduced three times at each overall concentration to within approximately ±0.5 MPa using a Heise digital pressure indicator (series 9, accurate to within ±0.07 MPa for data to 68.9 MPa) and at each temperature (held to within ±0.5 °C, using a type K thermocouple).

Copolymers with higher proportions of TFE (46.7 mol %) were expected to be more difficult to dissolve in CO2. Therefore, the phase behavior of these copolymers was considered with equipment rated to significantly higher pressures. The apparatus and techniques used to obtain these polymer–fluid phase behavior data were described elsewhere. The main component of the experimental apparatus was a high-pressure, variable-volume cell (Nitronic 50, 7.0 cm o.d. × 1.6 cm i.d., ~30 cm3 working volume). The cell was first loaded with a measured amount of copolymer to within ±0.002 g. To remove entrapped air, the cell was degassed very slowly at pressures less than 0.028 MPa with the CO2 then transferred into the cell gravimetrically to within ±0.02 g using a high-pressure bomb. The mixture in the cell was viewed with a borescope (Olympus Corp., model no. F100-024-000-55) placed against a sapphire window secured at one end of the cell. A stir bar activated by a magnet located below the cell mixed the contents of the cell. The solution temperature was held to within ±0.3 °C, as measured with a type K thermocouple. A fixed copolymer concentration of approximately 5 wt % was used for each constant-concentration, phase boundary curve. The mixture in the cell was compressed to a single phase, and the pressure was then slowly decreased until a second phase appears. The transition was a cloud point if the solution becomes so opaque that it was no longer possible to see the stir bar in solution. These cloud points had been compared in our laboratories to those obtained using a laser light setup where the phase transition was the condition of 90% reduction in light transmitted through the solution. Both methods gave identical results within the reproducibility of the data. The cloud-point transitions at this concentration were expected to be close to the maximum in the pressure–composition isotherms. The system pressure was measured with Heise pressure gauges accurate to within ±0.07 MPa for data to 69 MPa and to within ±0.35 MPa for data from 69 to 276 MPa. Cloud points were reproduced two to three times to within approximately ±0.42 MPa.

**Molecular Modeling Theory**

Although the interplay of solute–solute, solute–solvent, and solvent–solvent interactions should be completely considered when the dissolution behavior of
polymers in CO$_2$ is being explored, we realize that the polymer—polymer interactions are also of great importance in determining the solubility of the polymer. However, the interaction energies between polymer segments cannot be computed at the same level of theory as the segment—CO$_2$ interactions because two polymer segments have too many atoms. If we use a lower level of theory, such as DFT, then the answers would be largely meaningless. To perform these calculations, better computational algorithms and faster computers are needed to develop. Therefore, we only calculated and estimated the binding energies between polymer segment and CO$_2$.

There have been a number of different efforts to model the thermodynamic properties of polymer—CO$_2$ mixtures. Generally speaking, these modeling techniques fall into three categories: equation-of-state modeling, statistical mechanical simulations, and ab initio calculations. Equation-of-state methods have not proved to be accurate enough to predict the phase behavior of polymer—CO$_2$ mixtures. In principle, one could compute virtually all the thermodynamic properties of polymer—CO$_2$ mixtures through statistical mechanical simulations. However, this requires very accurate molecular interaction models, which are currently not available, especially for the CO$_2$—polymer cross-interactions. Another alternative is to bypass the use of potential models and directly use ab initio methods to generate the forces required for a simulation, such as is done in quantum molecular dynamics, but this is impractical for polymer—CO$_2$ mixtures because of the large system sizes and weak interactions among the molecules. Weak interactions (such as dispersion or van der Waals forces) are difficult to compute from ab initio methods because high-level methods and large basis sets are needed to capture electron dispersion. Computationally efficient methods, such as density functional theory, are known to be generally inadequate for computing van der Waals interactions. The Möller–Plesset (MP) perturbation method for including electron correlation has been used for weakly interacting systems but is known to have convergence problems. MP2 (second-order Möller–Plesset perturbation theory) is the lowest order MP theory and is not generally adequate for computing intermolecular interaction energies, except when a substantial electrostatic interaction is involved. Methods that include triple excitations, e.g., fourth-order Möller–Plesset with single, double, triple, and quadruple excitations MP4 (SDTQ), or coupled cluster with perturbational triples, CCSD(T), are required for many applications. However, recent work indicates that failure of MP2 may in part be due to basis set superposition error.

In this work we perform MP2 calculations to compute the interaction energies of CO$_2$ with various polymer fragments. Our aim is to determine the role of fluorine atoms in the backbone of the polymer on enhancing the solubility of the fluorinated copolymers in CO$_2$. We expect the MP2 method to be adequate for our purposes because we are interested in relative interaction energies for CO$_2$ on fluorinated and nonfluorinated polymer moieties; relative energies are expected to be more accurate than absolute energies. Furthermore, the presence of fluorine atoms on the polymer should increase the relative importance of electrostatic interactions, making the problem more appropriate for the MP2 method. Our previous calculations indicate that MP2 energies are fairly close to CCSD(T) energies for similar systems.

It is not possible to explicitly perform ab initio calculations on a polymer because of the large number of atoms. We therefore break the copolymer into small model segments. We then compute optimized geometries and binding energies for CO$_2$ interacting with these model segments. We performed geometry optimizations at the MP2/6-31+g(d) level of theory for a number of different polymer segment/CO$_2$ dimers. This relatively small basis set was used to make the optimizations feasible on the available computing resources. The optimized configurations were then used to calculate the more accurate single-point binding energies at larger basis set, aug-cc-pVDZ. This basis set still has significant basis set superposition error (BSSE), which is the spurious lowering of the binding energy due to the use of incomplete basis set. We have used standard counterpoise (CP) corrections to approximately account for BSSE. The binding energy was computed from the supermolecule approach

$$E_b = E(12) - E(1) - E(2) \quad (1.1)$$

where $E_b$ is the binding energy, $E(12)$ is the total energy of the dimer (CO$_2$ + polymer segment), and $E(i)$ is the energy of the isolated CO$_2$ or polymer segment molecule. Binding energies defined in this way are negative for energetically favorable dimers. We use the average of the raw and CP corrected interaction energies as an approximation to the complete basis set limit interaction energies. We do this to avoid the computationally expensive complete basis set extrapolation. This method has been tested by us previously for similar systems and found to be in good agreement with the results of Feller and Jordon. All binding energies reported in this paper are averages of the MP2/aug-cc-pVDZ corrected and uncorrected interaction energies. We have computed localized charge distributions for several of the model polymer segments using the NBO method. All calculations were performed with the Gaussian 98 package, revision A11.

### Results

#### Experimental Results

A series of TFE-co-VAc copolymers were synthesized in supercritical CO$_2$ and characterized for yield, bulk composition, molar mass, and $T_g$, the results of which are summarized in Table 1. As shown, a series of copolymer compositions were prepared where monomer feed composition influenced polymer composition, from 11.6 to 63.3 mol % TFE. The yield (based on mass) was high for all compositions between 78 and 86%. The $T_g$ was similar for all samples between 36 and 38 °C, which is similar to that of PVAc (38 °C). Since we were interested in comparing solubility in CO$_2$ as a function of copolymer composition, the

$^a$ Determined from mol % C elemental analysis. $^b$ Measured using ethyl acetate as mobile phase. Entries 1–4 were subsequently evaluated after the mobile phase was changed to THF.
samples were synthesized in such a manner to yield similar molecular weight characteristics, with $M_w$ between 140 and 180 kg/mol and the polydispersity index (PDI) between 2.7 and 3.1. For 63.3 mol % TFE copolymer, however, $M_w$ was higher and PDI lower than the other samples. It is important to note that this sample was measured by GPC in ethyl acetate whereas the other polymers were measured in THF. Ethyl acetate may have affected the hydrodynamic radius of the copolymer differently from THF, thereby accounting for the greater $M_w$ and smaller PDI.

The phase behavior of poly(TFE-co-VAc)–CO₂ mixtures was strongly influenced by the copolymer composition. (The copolymer will hereafter be designated as TFE-co-VAc, with the value of the TFE subscript corresponding to the mole fraction of that monomer.) The three copolymers with the smallest proportion of TFE, TFE11.6-co-VAc, TFE19.3-co-VAc, and TFE26.5-co-VAc, melt-flowed in CO₂ when heated above their $T_g$'s, as did the PVAc homopolymer (these are amorphous polymers). Like PVAc, these copolymers dissolved in the presence of liquid CO₂, and the general nature of the corresponding pressure–composition ($P-x$) diagram for such systems is illustrated in Figure 1.16 (Although this figure strictly applies to binary systems in which no CO₂ dissolves in a monodisperse crystalline polymer, the region bounded by the dashed line in Figure 1 illustrates the qualitative features of the mixtures of CO₂ with the polymers used in this study.) The small box within Figure 1 illustrates the region where the CO₂-rich liquid-polymer-rich liquid data were measured. The results, shown in Figure 2, indicate that these three TFE–VAc copolymers are more CO₂-soluble than PVAc as evidenced by the cloud-point curves of these copoly-
Because of the relatively low TFE content and copolymerization technique, the probability of lengthy block segments of TFE is low in these copolymers, and hence the propensity to crystallize and form CO₂-insoluble polymers is low.

The copolymers with higher concentrations of TFE, TFE₄₆.₇-co-VAc, and TFE₆₃.₃-co-VAc were markedly less CO₂-soluble. TFE₄₆.₇-co-VAc was insoluble in CO₂ at temperatures below 75 °C, which is notably less CO₂ soluble than the three copolymers with lower TFE concentrations; however, the copolymer did dissolve at elevated temperatures. At a copolymer concentration of 5 wt % in CO₂—a representative mixture composition that typically yields a cloud point pressure at or near the maximum cloud-point pressure of this portion of the phase diagram—cloud-point pressures were observed at higher temperatures. The cloud point pressure was found to be 74 MPa at 75 °C and 91 MPa at 128 °C (see Figure 3). However, TFE₆₃.₃-co-VAc does not dissolve in CO₂ even at 144 °C and 210 MPa. This may be due in part to the increased crystallinity of the copolymer associated with TFE-rich regions or blocks.

**Molecular Modeling Results.** We have employed ab initio molecular modeling to identify reasons for the enhanced solubility of TFE-co-VAc relative to the PVAc homopolymer. Figure 4b illustrates that the fluorinated carbons in the copolymer backbone will be adjacent to either a methylene carbon or a methyne carbon from which the pendant -OCOCH₃ group extends. We take one representative portion of TFE-co-VAc with a relatively small concentration of TFE shown in Figure 4c and divide it into three small molecules, shown in Figure 4d, which are conducive to molecular modeling calculations. First, we cut the molecule between the two CF₂ functional groups, yielding two fluorous molecules, 3,3,3-trifluoroisopropyl acetate (TFIPA) and 4,4,4-trifluoro-sec-butyl acetate (TFSBA). The third small molecule is 2,2,3,3-tetrafluorobutane (FB), which is a model for the backbone of the polymer. The hydrocarbon analogues of these small molecules, shown in Figure 4e, are isopropyl acetate (IPA), sec-butyl acetate (SBA), and n-butane. These molecules are used for direct comparisons with the semifluorinated compounds.

We have identified four possible binding configurations for CO₂ interacting with TFIPA and TFSBA. We use the TFIPA molecule as an example to illustrate the possible binding configurations because TFSBA has similar CO₂ binding configurations. The specific binding configurations are illustrated in Figure 5 as (A) ester oxygen, (B) carbonyl oxygen, tilted toward the methyl group, (C) carbonyl oxygen, tilted toward the ester group, and (D) backbone fluorine atoms. Geometry optimizations were started by placing the CO₂ molecule at various positions around the TFIPA and TFSBA molecules. From five to eight different starting geometries were used for each of the polymer fragments. The hydrocarbon analogues, IPA and SBA, were studied in the same way.

TFIPA/CO₂ and IPA/CO₂. Binding configuration A has an interaction energy of −15.9 kJ/mol. The optimized geometry for binding configuration A is shown in Figure 6. The dashed lines indicate interaction points between the two molecules. The atom–atom distances...
in angstroms are also shown. The carbon atom of the CO₂ molecule binds with both the fluorine atom and the ester oxygen atom on TFIPA in this configuration. Each oxygen on CO₂ interacts with a hydrogen in what can be termed a weakly hydrogen-bonding configuration.²⁷ We identify configuration A as quadradentate binding because the CO₂ molecule has four interaction points with the polymer moiety. In configurations B and C, the CO₂ molecule mainly interacts with the carbonyl oxygen atom of the TFIPA. This gives interaction energies that are quite similar to those between IPA and CO₂. Figure 5 shows the interactions for configuration D. This is also a quadradentate binding configuration. The carbon of the CO₂ interacts with two fluorine atoms while one oxygen of the CO₂ interacts with two hydrogens.

The binding energies for the four TFIPA/CO₂ binding configurations are listed in Table 2, along with the interaction energies for CO₂ with the hydrocarbon analogue, IPA. There is a difference of about 1.2 kJ/mol between the binding energies of TFIPA/CO₂ and IPA/CO₂ for configurations A and B. This energy difference is within the estimated accuracy of the ab initio calculations. The limited accuracy is due to lack of convergence in the theoretical method (MP2) and the choice of basis set. Thus, we conclude that the fluorine atoms on the polymer backbone do not substantially affect (positively or negatively) the binding energies of CO₂ with the acetate side chain.

We have not been able to find a configuration D for the IPA/CO₂ system, even though we started from several different initial configurations. In every case, the CO₂ molecule always migrates around the molecule to bind with the carbonyl or ester oxygen of the IPA molecule. This implies that there is no minimum corresponding to binding configuration D for the IPA/CO₂ system. However, the D geometry of the TFIPA/CO₂ system shows a considerable binding energy of –9.6 kJ/mol. This additional binding site for the TFIPA/CO₂ system is probably one of the main reasons for the increase in solubility of the TFE-co-VAc molecule in CO₂. Note that configuration D requires a junction between fluorinated and nonfluorinated segments. We estimate that at least two CO₂ molecules can favorably interact with each CF₂–CH₂ junction. Clearly, a moderate fraction of TFE in the copolymer would favor higher CO₂ solubility, since the number of CF₂–CH₂ junctions per polymer molecular weight is maximized for moderate mole fractions of TFE.

TFSA/CO₂ and SBA/CO₂. The TFSA/CO₂ system was investigated using similar binding configurations from A to D of the TFIPA/CO₂ system. The SBA/CO₂ system was used for comparison. Table 3 lists the calculated binding energies for these systems. The calculations for TFIPA/CO₂ and IPA/CO₂ indicate that the binding energies for configurations B and C should be similar for the fluorinated and nonfluorinated segments. We therefore did not calculate binding energies for configurations B and C for the SBA/CO₂ system. We used the values of the binding energies for configurations B and C from the IPA/CO₂ system as an estimate for the binding energies for SBA/CO₂ for the same configurations. The binding energy of configuration A for TFSA/CO₂ is –18.8 kJ/mol, which is much larger than the binding energy of configuration A for TFIPA/CO₂.
than the binding energies for any site of any of the other systems. Note from Table 3 that the interaction energy for configuration A of TFSBA is 2.5 kJ/mol more attractive than for SBA. This difference is larger than the expected uncertainty in the calculations.

We have examined the NBO charge distributions of TFSBA and other molecules in order to determine the origin of the enhanced binding for configuration A of TFSBA/CO₂. The local charges on atoms of TFSBA are shown in Figure 8. Note that the charge on hydrogens H(1) and H(2) is about 0.26. This is significantly larger than on hydrogens in the same positions on SBA or on hydrocarbons, which is about 0.23. Thus, hydrogens H(1) and H(2) are more acidic than typical hydrocarbon hydrogens. This is due to the fact that they are on the carbon that is beta to the highly electronegative fluorines. Configuration A on TFSBA/CO₂ is a quadridentate binding site, with one CO₂ oxygen interacting with H(1). The acidic hydrogen acts as a better Lewis acid for the CO₂ oxygen Lewis base. This, we believe, is the reason for the enhanced binding of configuration A for TFSBA/CO₂.

The charges on the two oxygen atoms of TFSBA are very similar to those of SBA. This is why the binding energies of configurations B and C are very similar for all the systems studied. Configuration D for the TFSBA/CO₂ system has a binding energy of −11.7 kJ/mol. This is larger than that for the same configuration on TFIPA/CO₂. We believe that the increase in binding energy is again due to the increased acidity of the hydrogens on the backbone. Note that our calculations could not locate a minimum for configuration D for SBA/CO₂, as was the case for IPA/CO₂.

FB/CO₂ and Butane/CO₂. To further investigate the interactions between the CO₂ molecule and the backbones of the polymers, FB and butane are used as models of the fluorinated and nonfluorinated backbones, respectively. Starting from several initial configurations, we identified a single geometry with the strongest interaction for each of the systems. Figure 9 shows the optimized binding geometries for the systems. The binding energies for butane/CO₂ and FB/CO₂ are −8.4 and −12.1 kJ/mol, respectively. The FB/CO₂ binding energy is 3.7 kJ/mol larger in magnitude than that for butane/CO₂. The hydrogen atoms involved in the interactions of the FB/CO₂ system are more acidic than those on typical hydrocarbons. The FB hydrogens have a charge of 0.256, compared with 0.216 for hydrogens on butane. The FB/CO₂ binding energy is close to the configuration D binding energy for TFSBA/CO₂ of −11.7 kJ/mol but stronger than that for TFIPA/CO₂ of −9.6 kJ/mol. The hydrogen atoms involved in the configuration D interactions have charges of 0.26 and 0.24 for TFSBA/CO₂ and TFIPA/CO₂ systems, respectively. These values are close to those for the FB/CO₂ system, indicating that the FB molecule is a reasonable surrogate for the backbone of the polymer. The enhanced binding of CO₂ with the semifluorinated molecules relative to nonfluorinated compounds indicates that the backbone of the semifluorinated polymers acts as effective simultaneous Lewis acids (H–O) and Lewis bases (F–C) toward CO₂. These interactions are likely to significantly enhance the solubility of the polymer compared with nonfluorinated analogues. Note also that the acidic hydrogens are only available on semifluorinated backbones. This corroborates the experimental observation that high fractions of TFE in the copolymer reduce the solubility.

Discussion

A CO₂ molecule can act simultaneously as both a Lewis acid and a Lewis base if the molecule with which it is interacting has both Lewis base and acid groups. Our molecular modeling results show that this is precisely the case for semifluorinated polymers such as TFE–VAc. Perfluorinated polymers lack Lewis acid sites and also exhibit very high melting points. Furthermore, O–F interactions are only weakly attractive.
since both the oxygens in CO$_2$ and the fluorine in the polymer are electron-rich. This is one of the major reasons that partially fluorinated polymers are more CO$_2$-philic than perfluorinated ones. Raveendran et al. have also observed enhanced binding of CO$_2$ with partially fluorinated molecules. They performed ab initio calculations on CO$_2$--CF$_n$H$_{4-n}$ for $n = 0$--4. They concluded that there may be an optimal density of fluorine atoms in a molecule leading to maximum CO$_2$-philicity. They attribute this optimal density to the competition among the individual electronegative fluorine atoms. In other words, fluorine atoms in highly fluorinated molecules are less effective electron donors. We believe this effect to be of minor importance compared with the requirement for a molecule to have both Lewis acid and base sites present in the correct geometry to interact simultaneously with CO$_2$. This is difficult to achieve in a small molecule like CF$_4$H$_{4-n}$. We note that Fried and Hu have also studied the binding of CO$_2$ on semifluorinated small molecules using ab initio calculations. They found that quadrupole–dipole interactions between CO$_2$ and the partially fluorinated molecules contribute significantly to the total interaction energy. Their results are in agreement with our calculations, showing that partially fluorinated molecules should be more soluble than perfluorinated species.

Another consideration is Wallen's claim that fluorination of methane makes the hydrogen atoms less acidic compared with hydrogen atoms in methane. This is not the case for larger molecules. The hydrogen atoms on the carbon $\beta$ to the fluorine atom are more acidic than the hydrogens on n-butane. NBO charges for hydrogens on FB and butane are about 0.26 and 0.22, respectively. The enhancement of H atom acidity relative to the hydrocarbon cannot be observed by studying semifluorinated methane.

Binding of CO$_2$ to carbonyl functional groups is virtually unaffected by the fluorination, as shown in Table 2. In contrast, Raveendran et al. noted that fluorination decreases the carbonyl CO$_2$-philicity of partially fluorinated acetaldehyde. Separation of the fluorine atoms from the carbonyl group by more than one carbon atom mitigates the effect of the fluorine on carbonyl–CO$_2$ binding, however. Note that the charges on the ester and carbonyl oxygens in both TFSA and SBA are almost identical, as shown in Figure 8.

**Summary**

High molecular weight poly(TFE-co-VAc) with TFE content ranging between 11.6 and 26.5 mol % required lower pressure for dissolution in CO$_2$ at 25 °C and at low concentrations (<6 wt %) than PVAc homopolymer. Further, these poly(TFE-co-VAc) copolymers were soluble to higher concentrations in CO$_2$ (7.4–10 wt %) than PVAc (6 wt %). The copolymer composed of 46.7 mol % TFE was not soluble in CO$_2$ at 25 °C but was CO$_2$-soluble at temperatures greater than 75 °C. The copolymer with 63.3 mol % TFE was insoluble in CO$_2$ at all conditions, possibly due to the presence of TFE blocks, which may be crystalline and thereby reduce solubility. Introduction of hexafluoropropylene units may disrupt this apparent crystallinity while maintaining the fluoro- carbon content and enhancing CO$_2$-solubility.

Ab initio calculations have revealed the following reasons for the increased solubility of poly(TFE-co-VAc) relative to PVAc. (1) The specific geometry and functionality of the polymer give rise to “quadradentate” binding of CO$_2$ to the polymer, having an interaction energy about 2.5 kJ/mol more favorable than the non-fluorinated analogue; compare configurations A in Table 3. (2) The interaction of CO$_2$ with the partially fluorinated backbone is 3.7 kJ/mol more favorable than with the hydrocarbon analogue. (3) The electron-withdrawing effects of the F atoms on the backbone renders nearby H atoms slightly more acidic, promoting stronger hydrogen bonding with the O atoms in CO$_2$. Finally, we note that CO$_2$ acts simultaneously as both a Lewis acid and a Lewis base for many of the binding geometries identified through molecular modeling.

**Acknowledgment.** We are grateful to the following agencies for partial support of this research: Natural Sciences and Engineering Research Council of Canada (M.S.S.), National Science Foundation (R.M.E.), and DOE National Energy Technology Laboratory and National Petroleum Technology Office (R.M.E.). Polymer syntheses were performed at the University of Toronto, ultrahigh-pressure phase behavior measurements were taken at VCU, and computations were performed at the University of Pittsburgh Center for Molecular and Materials Simulations.
